Java Configuration

Dependency Injection using Spring

Module Objectives

After completing this lesson, you should be able to do the following

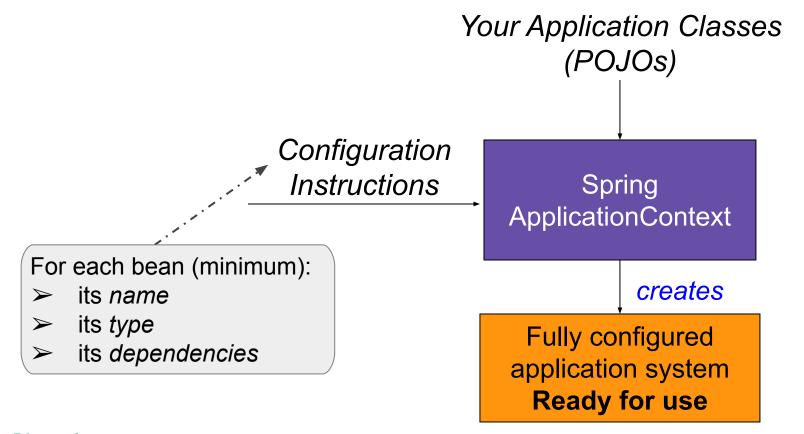

- Define Spring Beans using Java code
- Access Beans in the Application Context
- Handle multiple Configuration files
- Handle Dependencies between Beans
- Explain and define Bean Scopes

Agenda

- Spring quick start
- Creating an application context
- Multiple Configuration Files
- Bean scope

How Spring Container Works

Your Application Classes as POJO's with Dependencies

```
public class TransferServiceImpl implements TransferService {
   public TransferServiceImpl(AccountRepository ar) {
      this.accountRepository = ar;
   }
   Dependency: Needed to perform money transfers between accounts
```

```
public class JdbcAccountRepository implements AccountRepository {
   public JdbcAccountRepository(DataSource ds) {
     this.dataSource = ds;
   }
   Dependency: Needed to access
   account data in the database
}
```

You do not have to use *interfaces* to define Spring Beans, but it is good Java practice as they encourage loose-coupling.

Configuration Instructions with @Configuration & @Bean

```
@Configuration
public class ApplicationConfig {
 @Bean public TransferService transferService() {
   return new TransferServiceImpl( accountRepository());
 @Bean public AccountRepository accountRepository() {
   return new JdbcAccountRepository( dataSource() );
 @Bean public DataSource dataSource() {
   BasicDataSource dataSource = new BasicDataSource();
   dataSource.setDriverClassName("org.postgresql.Driver");
   dataSource.setUrl("jdbc:postgresgl://localhost/transfer");
   dataSource.setUsername("transfer-app");
   dataSource.setPassword("secret45");
   return dataSource;
```

Creating and Using the Application

```
What configuration to
// Create application context from the configuration
                                                                   use to define beans
ApplicationContext context =
  SpringApplication.run(ApplicationConfig.class);
                                                                        Bean ID
// Look up a service
                                                                 Based in method name
TransferService service =
       context.getBean("transferService", TransferService.class);
// Use the service
service.transfer(new MonetaryAmount("300.00"), "1", "2");
```

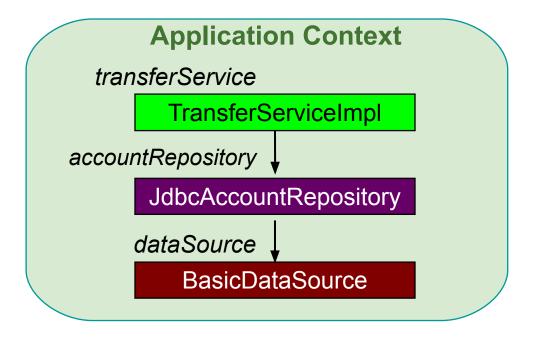

Note that Spring will create *four* beans: **ApplicationConfig** is *also* a Spring Bean - it is used to create the others.

Accessing a Bean Programmatically

Multiple options ApplicationContext context = SpringApplication.run(...); // Use bean id, a cast is needed TransferService ts1 = (TransferService) context.getBean("transferService"): // Use typed method to avoid cast TransferService ts2 = context.getBean("transferService", TransferService.class); // No need for bean id if type is unique TransferService ts3 = context.getBean(TransferService.class);

Inside the Spring Application Context

// Create application context from the configuration
ApplicationContext context = SpringApplication.run(ApplicationConfig.class)

Quick Start Summary

- Spring separates application configuration from application objects (beans)
- Spring manages your application objects
 - Creating them in the correct order
 - Ensuring they are fully initialized before use
- Each bean is given a unique id / name
 - Should reflect service or role the bean provides to clients
 - Bean ids should not contain implementation details

Agenda

- Spring quick start
- Creating an application context
- Multiple Configuration Files
- Bean scope

Creating a Spring Application Context

- Spring application contexts can be bootstrapped in any environment, including
 - JUnit system test
 - Web application
 - Standalone application

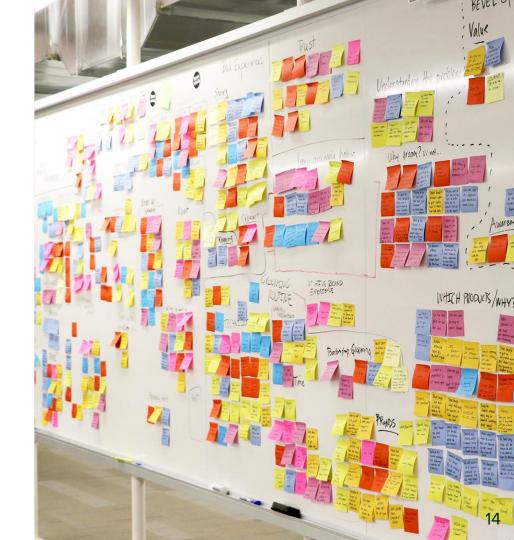

Application Context Example

Instantiating Within an Integration or System Test

```
public class TransferServiceTests {
  private TransferService service;
                                                                       Bootstraps the
                                                                        system to test
  @BeforeEach public void setUp() {
    // Create application context from the configuration
    ApplicationContext context =
      SpringApplication.run( ApplicationConfig.class )
    // Look up a service
    service = context.getBean(TransferService.class);
                                                                       Tests the system
  @Test public void moneyTransfer() {
    Confirmation receipt =
      service.transfer(new MonetaryAmount("300.00"), "1", "2"));
    Assert.assertEquals("500.00", receipt.getNewBalance());
                            Using JUnit 5 – JUnit 4 or TestNG also supported
```

Agenda

- Spring quick start
- Creating an application context
- Multiple Configuration Files
- Bean scope

Creating an Application Context from Multiple Files

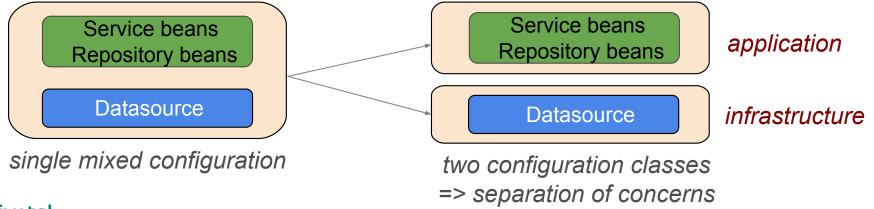

- Your @Configuration class can get too big
 - Instead use multiple files combined with @Import
 - Defines a <u>single</u> Application Context

```
    Beans sourced from multiple files

                                                                         Keep related
           @Configuration
                                                                        beans together
           @Import({ApplicationConfig.class, WebConfig.class })
           public class InfrastructureConfig {
@Configuration
                                                 @Configuration
public class ApplicationConfig {
                                                 public class WebConfig {
```

Creating an Application Context from Multiple Files

- Separation of Concerns principle
 - Keep related beans in the same @Configuration
- Best Practice: separate "application" & "infrastructure"
 - Infrastructure often changes between environments

Pivotal

Mixed Configuration

```
@Configuration
public class ApplicationConfig {
                                                                          application beans
  @Bean public TransferService transferService()
    { return new TransferServiceImpl( accountRepository() ); }
 @Bean public AccountRepository accountRepository()
                                                                                Coupled to a
    { return new JdbcAccountRepository( dataSource() ); }
                                                                               local Postgres
                                                                                environment
 @Bean public DataSource dataSource() {
   BasicDataSource dataSource = new BasicDataSource();
   dataSource.setDriverClassName("org.postgresql.Driver");
   dataSource.setUrl("jdbc:postgresql://localhost/transfer");
   dataSource.setUsername("transfer-app");
   dataSource.setPassword("secret45");
   return dataSource:
                                                                         infrastructure bean
```

Partitioning Configuration

```
application beans
@Configuration
public class ApplicationConfig {
 @Bean public TransferService transferService(AccountRepository repo) {
   return new TransferServiceImpl ( repo );
 @Bean public AccountRepository accountRepository(DataSource ds) {
   return new JdbcAccountRepository( ds );
                                                             Infrastructure config
         @Configuration
                                                            imports all the others
         @Import(ApplicationConfig.class)
         public class TestInfrastructureConfig {
           @Bean public DataSource dataSource() {
                                                                     infrastructure bean
              ApplicationContext ctx = SpringApplication.run( TestInfrastructureConfig.class )
```

Pivotal

Referencing Dependencies 1 - Via Autowired

Use @Autowired to inject a bean defined elsewhere

```
@Configuration
public class ApplicationConfig {
 private final DataSource dataSource;
                                                       @Configuration
                                                       @Import(ApplicationConfig.class)
 @Autowired
                                                      public class InfrastructureConfig {
 public ApplicationConfig(DataSource ds) {
                                                        @Bean
  this.dataSource = ds:
                                                        public DataSource dataSource() {
                                                          DataSource ds = new BasicDataSource();
 @Bean
                                                          return ds;
 public AccountRepository accountRepository() {
  return new JdbcAccountRepository( dataSource );
```

Referencing Dependencies 2 - Via Arguments

- Alternative: Define @Bean method arguments
 - Spring finds bean that matches type & injects the argument

```
@Configuration
public class ApplicationConfig {
 @Bean
 public AccountRepository accountRepository( DataSource dataSource ) {
  return new JdbcAccountRepository( dataSource );
                                        @Configuration
                                        @Import(ApplicationConfig.class)
                                        public class InfrastructureConfig {
                                         @Bean public DataSource dataSource() {
                                           DataSource ds = new BasicDataSource();
                                           return ds;
```

... But Avoid "Tramp Data"

```
Bad: dataSource is a "tramp"!
 @Configuration
 public class ApplicationConfig {
   @Bean public AccountService accountService( DataSource ds ) {
    return new AccountService( accountRepository(ds) );
                                               tramp
   @Bean public AccountRepository accountRepository ( DataSource ds ) {
    return new JdbcAccountRepository( ds );
                                                                 Better: Pass actual dependency
               @Configuration
               public class ApplicationConfig {
                @Bean public AccountService accountService (AccountRepository repo ) {
                  return new AccountService( repo );
                @Bean public AccountRepository accountRepository ( DataSource ds ) {
                  return new JdbcAccountRepository( ds );
Pivota
```

Bean Overriding

Recall: bean name from method name

- Defines same bean more than once
 - Allows override when testing: you get the *last* bean Spring sees defined
- Disabled by default from Spring Boot 2.1
 - To prevent a bean being accidentally overridden.
 - Set spring.main.allow-bean-definition-overriding=true to enable it

```
@Configuration
                                                                    @Configuration
public class Config1 {
                                                                    public class Config2/{
 @Bean
                                                                      @Bean
                                                                      public String example() {
 public String example() {
   return new String("example1");
                                                                        return new String("example2");
       @Import({ Config1.class, Config2.class })
      public class TestApp {
        public static void main(String[] args) {
          ApplicationContext context = SpringApplication.run(TestApp.class);
          System.out.println("Id=" + context.getBean("example"));
```

Console output is *Id=example2*

Agenda

- Spring quick start
- Creating an application context
- Multiple Configuration Files
- Bean scope

Bean Scope: Default

service1 == service2

Default scope is singleton

```
@Bean
                                                         These are equivalent
public AccountService accountService() {
   return ...
                                         @Bean
                                         @Scope("singleton")
                                         public AccountService accountService() {
                                            return ...
   One single instance
 AccountService service1 = (AccountService) context.getBean("accountService");
 AccountService service2 = (AccountService) context.getBean("accountService");
 assert service1 == service2; // True - same object
```

Implications for Singleton Beans

- Typical Spring application back-end web-server
 - Multiple requests in parallel
 - Handled by multiple threads
 - Implications:
 - Multiple threads accessing singleton beans at the same time
- Consider multi-threading issues
 - Stateless or Immutable beans
 - synchronized (harder)
 - Use a different scope

Bean Scope: prototype

service1 != service2

- Scope "prototype"
 - New instance created every time bean is referenced

```
@Bean
@Scope("prototype")
public Action deviceAction() {
    return ...
}
@Scope(scopeName="prototype")
```

```
Action action1 = (Action) context.getBean("deviceAction");
Action action2 = (Action) context.getBean("deviceAction");
assert action1!= action2; // True – different objects

TWO instances
```

Common Spring Scopes

The most commonly used scopes are:

singleton	A single instance is used
prototype	A new instance is created each time the bean is referenced
session	A new instance is created once per user session - web environment only
request	A new instance is created once per request – web environment only

Pivotal

Other Scopes

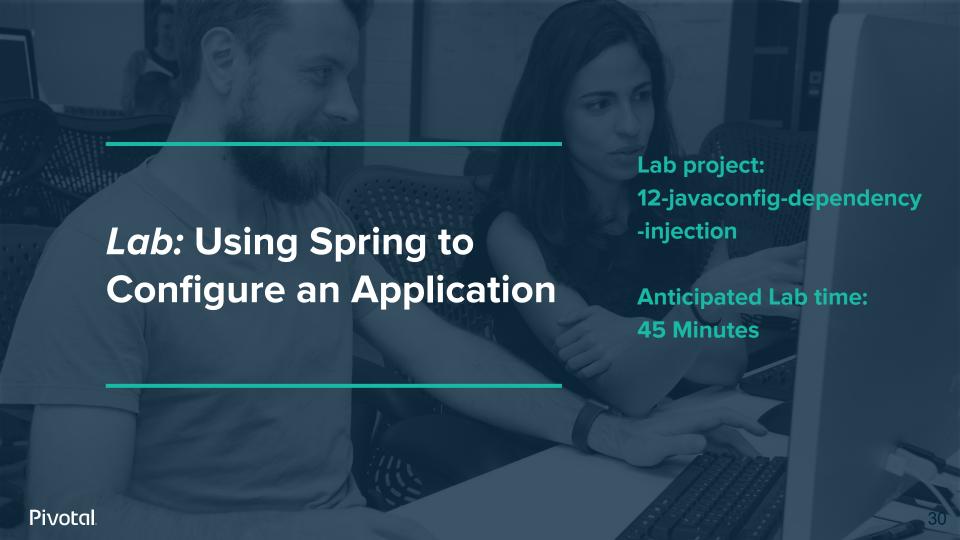

- Spring has other more specialized scopes
 - Web Socket scope
 - Refresh Scope
 - Thread Scope (defined but not registered by default)
- Custom scopes (rarely)
 - You define a factory for creating bean instances
 - Register to define a custom scope name

These scopes are not covered by this course, but see Scope reference slide at end of this section

Dependency Injection Summary

- Your object is handed what it needs to work
 - Frees it from the burden of resolving its dependencies
 - Simplifies your code, improves code reusability
- Promotes programming to interfaces
 - Conceals implementation details of dependencies
- Improves testability
 - Dependencies easily stubbed out for unit testing
- Allows for centralized control over object lifecycle
 - Opens the door for new possibilities

Reference: Available Scopes

Scope	Description
singleton	Lasts as long as its ApplicationContext
prototype	getBean() returns a new bean every time. Lasts as long as you refer to it, then garbage collected
session	Lasts as long as user's HTTP session
request	Lasts as long as user's HTTP request
application	Lasts as long as the ServletContext (Spring 4.0)
global	Lasts as long as a global HttpSession in a Portlet application (obsolete from Spring 5)
thread	Lasts as long as its thread – defined in Spring but not registered by default
websocket	Lasts as long as its websocket (Spring 4.2)
refresh	Can outlive reload of its application context. Difficult to do well, assumes Spring Cloud Configuration Server

Pivotal.
